#### Abstract

A spreadsheet program, such as Microsoft Excel, has proven to be an excellent tool for the study, implementation, and visualization of a wide range of mathematical concepts, as well as for mathematical modeling of diverse applications. We focus on the use of Excel's powerful Data Table tool to present new and creative ways to study and teach a wide range of mathematical topics. We draw our topics from algebra, calculus, linear algebra, probability, statistics, and numerical analysis. Each is accompanied by files that incorporate interactive graphics created in Excel. We also present additional ideas for educators and their students to pursue.

## Introduction

Ever since the initial spreadsheet program, VisiCalc, was launched in 1980, and especially following the inclusion of added features and graphic capabilities in subsequent spreadsheets, the educational community has constantly found innovative ways to use spreadsheets for the study and teaching of mathematics [1,2,5,7]. In this paper we provide some examples for the creative use of the Data Table tool of Excel and other spreadsheets for the study and teaching of mathematics, and provide suggestions for further areas of application of this valuable tool.

## Example 1. Geometric Growth

To describe the use of the Data Table command, our first example is a standard compound interest model [5]. It is often advantageous to introduce a new topic through the use of a familiar example that we can also examine using other methods, thereby allowing us to both verify and compare the approaches. Our model assumes that we enter a one-time deposit that earns annual compound interest at a given rate for 10 years.

In Figure 1(a) we first enter the principal and annual interest rate in Cells B1:B2. We use Column A to count years, while we find the annual starting balance and interest in Columns B-C. In Figures 1(a) and 1(b) we see the resulting output and the underlying formulas in Columns A:C. Cell B15 contains the resulting $10^{\text {th }}$ year balance.

Now, suppose that we want to create a summary of the $10^{\text {th }}$ year balance for different annual interest rates. Of course, we could simply change cell B2 repeatedly, and manually write down the resulting balance. However, the Data Table command can do this for us automatically. We create the data table in the Block E5:F15. In Column E we leave the top cell E5 blank, and then enter in the rest of Column E the interest rates that we desire to examine. While we have used formulas to increment the rates in steps of $1 \%$, we can enter whatever rates are desired. In Cell F5, we enter a formula, $=$ B15, that reproduces the 10-year balance for the current rate.

To issue the Data Table command, we first use our selection device to select the Block E5:F15, as shown in Figure 2. We then select the Excel command options Data, What If Analysis, Data Table. In the resulting Data Table display, we click in the Column Input cell box, and then click on the rate cell, B2. After we then click on OK, Excel repeatedly inserts each of the rate values in Column E into Cell B2, and records the corresponding $10^{\text {th }}$ year balances in Column C, as shown in Figure 1(c).

Figure 1(c). Data Table

Figure 2. Data Table Display
If this is the first time for someone to use the Data Table, it is a good exercise to create an additional column of the $10^{\text {th }}$ year values by using the closed formula $P(1+r)^{10}$ or one of Excel's built-in financial functions. We shall then see that the result agrees with our Data Table model.

Students can also find similar uses for the data table in the study of annuities and other financial applications, as well as in such areas as population growth and the spread of epidemics. We leave the Excel file in [S1] for readers to explore further.

## Example 2. Cramer's Rule

Cramer's Rule [9] is a well-known procedure that uses determinants to solve a linear system of $n$ equations in $n$ unknowns. Unfortunately, doing this procedure by hand is both tedious and very inefficient for $n>3$. However, using Excel's determinant and matrix functions, together with the Data Table tool, makes the process quite accessible and efficient, even for rather large values of $n$.

For an $n \times n$ system,

$$
\begin{aligned}
& a_{11} x_{1}+a_{12} x_{2} \ldots+a_{1 k} x_{k} \ldots+a_{1 n} x_{n}=c_{1} \\
& a_{21} x_{1}+a_{22} x_{2} \ldots+a_{2 k} x_{k} \ldots+a_{2 n} x_{n}=c_{2} \\
& a_{i 1} x_{1}+a_{i 2} x_{2} \ldots+a_{i k} x_{k} \ldots+a_{i n} x_{n}=c_{i} \\
& a_{n 1} x_{1}+a_{n 2} x_{2} \ldots+a_{n k} x_{k} \ldots+a_{n n} x_{n}=c_{n}
\end{aligned}
$$

Cramer's Rule states that the value, $x_{k}$, of the $k^{\text {th }}$ component of the solution, can be found by dividing the determinant that results by replacing the entries of the $k^{\text {th }}$ column of the $n \times n$ matrix of coefficients with the column of constants by the determinant of the coefficients, or

$$
x_{k}=\left|\begin{array}{cccccc}
a_{11} & a_{12} & \ldots & c_{1} & \ldots & a_{1 n} \\
a_{21} & a_{22} & \ldots & c_{2} & \ldots & a_{2 n} \\
\ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\
a_{i 1} & a_{i 2} & \ldots & c_{i} & \ldots & a_{i n} \\
\ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\
a_{n 1} & a_{n 2} & \ldots & c_{n} & \ldots & a_{n n}
\end{array}\right| /\left|\begin{array}{cccccc}
a_{11} & a_{12} & \ldots & a_{1 k} & \ldots & a_{1 n} \\
a_{21} & a_{22} & \ldots & a_{2 k} & \ldots & a_{2 n} \\
\ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\
a_{i 1} & a_{i 2} & \ldots & a_{i k} & \ldots & a_{i n} \\
\ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\
a_{n 1} & a_{n 2} & \ldots & a_{n k} & \ldots & a_{n n}
\end{array}\right|
$$

In Figure 3 we illustrate our procedure for the $5 \times 5$ case. We enter the system in the block A4:F8 with Row 3 used as a counter for $k$. We then enter a value for $k$ in Cell D1. In the block A10:F14 the entries in Column $k$ of A are replaced by the column of constants to produce the matrix $A_{k}$. To do this, in Cell A10 we enter $=\operatorname{IF}(\mathrm{A} \$ 3=\$ \mathrm{D} \$ 1, \$ \mathrm{~F} 4, \mathrm{~A} 4)$, and then copy it throughout the Block A10:E14. We compute the determinant of $A$ in Cell B1 by $=\operatorname{MDETERM}(\mathrm{A} 4: \mathrm{E} 8)$ and the determinant of $A_{k}$ in Cell F1 by =MDETERM(A10:E14).

We next create the Data Table in the Block I3:J8, entering the formula $=\mathrm{F} 1 / \mathrm{B} 1$ for $\left|A_{k}\right| /|A|$ in Cell J 3 , and values for $k=1,2,3,4,5$ down Column I. We then issue the Data Table command, selecting the Block I3:J8 and Column Input Cell, D1. Figure 3(b) shows the resulting display. Modifying the design for larger systems is straightforward. We have used this successfully for systems of as many as 20 variables.

Experimenting with the size of the system makes a good related project, as will discovering other uses in linear algebra and matrix theory for Excel's determinant function. We leave the Excel file in [S2] for readers to explore further.

## Example 3. Numerical Integration via Trapezoidal Rule

Here we present the use of the Data Table tool to significantly condense lengthy series of calculations. In calculus we examine a variety of ways to approximate a definite integral as the area beneath a curve. Using the trapezoidal rule [4,8], we approximate the area under equally-spaced segments of a continuous curve by trapezoids, as shown in Figure 4(a), using the formula $A \approx(b-a)(f(a)+f(b)) / 2$.

Figure 4(a). Trap: $n=1$

Figure 4(b). Trap: $n=3$

Figure 4(c). Trap: $n=9$

We use the trapezoidal rule to obtain an approximation for an integral by dividing the interval [ $a, b$ ] into $n$ equal subdivisions. As $n$ increases we will get increasingly better approximations until round-off error intrudes. However, it can be inconvenient or impossible to increase the number of rows in a spreadsheet model beyond a certain number of divisions. We can overcome much of this difficulty by using a Data Table. For our illustration, we use the function: $f(x)=1 / x^{2}, 1 \leq x \leq 3$. $f(x)=1 / x^{2}, 1 \leq x \leq 3$. Here we carry out 10,000 computations by using only 1,000 cells.

In Column B of Figure 5(a) we enter the number, $n$, of major subdivisions (here $n=10$ ) and the values of $a$ and $b$. We also compute the interval width $b-a$, the subdivision width or gap as gap $=(b-a) / n$. We divide each major subdivision into 1000 small divisions, using a step size of step $=$ gap $/ 1000$. Next, in Columns D:I we compute the trapezoidal areas for the small segments of the interval starting with the entry in Cell E3. We leave details left to readers. The basic Trapezoidal Rule formulas are given in Figure 6.

We now create a 10 -step Data Table in Columns L:M. Column L consists of the major interval starting points. In Cell M3 we compute the sum of Column I as $=\mathrm{SUM}($ I3:I1002). We then issue the Data Table Command, using E3 as the Column Input cell. After this the overall resulting area approximation is found in Cell M15 as $=\operatorname{SUM}(\mathrm{M} 4: \mathrm{M} 13)$. We then reproduce this in Column A where we compare it with exact area found by integration. Figure 5(b) shows the initial Data Table.

Figure 6. Trapezoidal Formulas
There are various other numerical integration algorithms (e.g., Simpson's method) that we can implement similarly. In addition, this is a good place to examine the topic of round-off and similar topics that arise in numerical analysis. We leave the Excel file in [S3] for readers to explore further.

## Example 4. Eigenvalues and Characteristic Polynomial

A major topic in linear algebra is that of eigenvalues and eigenvectors of matrices [9]. A real number, $\lambda$, is an eigenvalue of an $n \times n$ real matrix $A$ if there is a non-zero vector $\vec{v}$ for which $A \vec{v}=\lambda \vec{v}$ . Any vector $\vec{v}$ that satisfies this equation is called an eigenvector corresponding to $\lambda$. To find the real eigenvalues of a square matrix $A$, we note that if $A \vec{v}=\lambda \vec{v}=(\lambda I) \vec{v}$, and $(A-\lambda I) \vec{v}=\overrightarrow{0}$. This happens when the determinant $|A-\lambda I|=0$. We use this fact to find the real eigenvalues of a $n \times n$ matrix $A$.

We illustrate our process in Figure 7 with a $4 \times 4$ matrix, and employ a data table to evaluate points of the characteristic polynomial $f(x)=|A-x I|$. The zeroes, $\lambda$, of this function then are the eigenvalues of $A$. We enter the values of $A$ in the Block $\mathrm{B} 2: \mathrm{E} 5$, and formulas to compute the entries of $A-\lambda I$ in the block B7:E10. We compute $|A-\lambda I|$ in Cell E1.

We next use the Data Table command to compute the $(x, y)$ coordinates of $f(x)$, with steps in the $x$ values of size 0.1 , over the interval $-4 \leq x \leq 4$. Cell B2 is the column input cell for the data table.

Figure 9(b). Estimate of Zeroes

Figure 9(c). Zeroes

From the graph of Figure 9(a), we can estimate manually the values of the eigenvalues as the points where the curve crosses the $x$-axis as in Figure 10(a). We then use the Data Table command again to get the $y$-values corresponding to these points, as shown in Figure 10(b) where we have used rough estimates of the zeroes of the function. We incorporate these into our graph as markers only in Figure 9(b). We could use estimates of $x$-values other than those in our given list.

Figure 10(c). Solver

We next use Excel's Solver command to find a better fit, as illustrated in Figure 10(c). To do this we compute the sum of the squares of the $y$-values that result from our estimates for $x$. In the Solver we set the goal of making the sum of the squares (Cell K8) to 0 by varying the $x$-values (I3:I6). We set the Solver type to GRG nonlinear. To ensure that no two of the values converge to the same zero, we include constraints such as, I3 $\leq-3$ and I3 $\geq-3.5$ in the Solver's Constraints section. We then press Solve to generate the estimates in Figures 9(c) and 10(c). As another valuable project, we also can implement traditional algorithms from numerical analysis [2] for computing eigenvalues and compare them with our results.

Our Data Table provides us with one more reward - a way to find the equation of the characteristic polynomial. This is especially useful when working with larger matrices. In our example we note that the characteristic equation will be a polynomial of degree $4, f(x)=a_{0}+a_{1} x+a_{2} x^{2}+a_{3} x^{3}+a_{4} x^{4}$. From out Data Table display we select five points $(x, f(x))$ and solve the resulting system. We use $x=0,1$, $2,3,4$, with the data table giving $f(0)=4, f(1)=-12, f(2)=-38, f(3)=-38, f(4)=48$. Thus,

$$
\begin{aligned}
& f(0)=a_{0} \\
& f(1)=a_{0}+a_{1}+a_{2}+a_{3}+a_{4} \\
& f(2)=a_{0}+2 a_{1}+4 a_{2}+8 a_{3}+16 a_{4} \\
& f(3)=a_{0}+3 a_{1}+9 a_{2}+27 a_{3}+81 a_{4} \\
& f(4)=a_{0}+4 a_{1}+16 a_{2}+64 a_{3}+256 a_{4}
\end{aligned}
$$

We then use Excel's matrix multiplication and inverse functions to solve the system. We obtain $f(x)=4-5 x-12 x^{2}+x^{4}$ and plot the graph of the function as a second carve in our earlier graph to see further that it agrees with the data table. This process is shown in our accompanying Excel files.

## Example 5. Calculus: Newton's Method

Newton's Method $[4,8]$ provides us with a means for estimating the zeroes of a differentiable function. Thus, if $y=f(x)$ is such a function, then we start with a reasonable estimate, $x_{0}$, of a zero. Next, as illustrated in Figure 11(a), we find where the tangent line to the curve at the point ( $\left.x_{0}, f\left(x_{0}\right)\right)$ intersects the $x$-axis, $x_{1}=x_{0}-f\left(x_{0}\right) / f^{\prime}\left(x_{0}\right)$. This will generally be a better approximation. We then repeat this process, which usually converges quickly to the desired zero. However, sometimes this method may fail to converge. Also, in some cases, even a small changes in the choice of $x_{0}$ can produce very different points of convergence, as shown in Figures 11(b) and 11(c), using $f(x)=\cos x$. We investigate this phenomenon in an Excel model using a data table.

Figure 11(a). Newton Figure 11(b). Newton $\left(x_{0}=0.30\right)$ Figure 11(c). Newton $\left(x_{0}=0.31\right)$
Figure 12 presents a model for Newton's Method in Columns A:D with $f(x)=\cos x$ and $f^{\prime}(x)=-\sin x$. We enter an initial estimate $x_{0}$ in Cell B1. This becomes the first value for $x$ in Cell B4. We find $f(x)$ and $f^{\prime}(x)$ in Columns C:D and the next value of $x$ in Column B of the following row. Our implementation extends through an extensive number of rows, by which time Newton's Method usually will have converged, say in Cell B24, to the resulting zero. Then in Columns F:G we create a data table for various initial $x_{0}$-values, using the resulting approximation from Cell B24 as the returned value.

We can see that if our initial estimate is $x_{0}=0.30$ then the algorithm will converge to $x \approx-4.71$ (i.e., $-3 \pi / 2$ ), while if $x_{0}=0.31$ then it converges to $x \approx 7.85$ (i.e., $5 \pi / 2$ ). We can study this phenomenon further by using a data table in Columns F:G. We generate a range of the initial values, $x_{0}$, down Column F with the resulting point of convergence $x_{1}$ in Column G . We produce the source of the $x_{1}$ values for the Data Table tool in Cell G4 as =B24.

Figure 13. Points of Convergence for Newton's Method

To complete our model, we create an $x y$-graph from Columns F:G plotting markers to get the picture of Figure 13 showing how the point of convergence varies for a range of initial estimates $x_{0}$. We leave the Excel file in [S5] for readers to explore further.

## Example 6 - Random Model of Coin Flip

We can use Excel's RANDOM function to simulate events and concepts that are included in the study of probability and statistics [10]. When combined with the Data Table tool, we are able to produce summaries of sets of repeated random trials. Here we create a simulation of 1000 sets of 100 flips of a fair coin (i.e., with probability $p=0.5$ of obtaining a head).

In the model of Figure 14 we count the flips in Column A and generate random numbers between 0 and 1 in Column B. We set the probability of success $p$ (here $p=0.5$ ) in Cell C2. Next, in Cell C5 we use the =IF function to generate a head, "H" if the current random number is less than $p$, and " T " otherwise. We then copy this expression down Column C. Next, in Cell C1 we determine the number of heads using the $=$ COUNTIF function. Finally, we create a data table in the Block E4:F1004 to find the number of heads in each of 1000 repetitions. In Cell F1 of the data table we use the =AVERAGE function to compute the mean number of heads in the 1000 flips.

It is also instructive to look at the distribution of the number of heads, $n$, obtained in the 1000 flips. We create this summary in Columns H:I using the =COUNTIF function. Here we have computed this for $30 \leq n \leq 70$ in order to produce the graph of Figure 16 that is broad enough to include all outcomes. We can simulate other binomial events by changing the value of $p$ in Cell C 2 . In this case we may need to modify the range of our graph. Designing similar simulation models for other discrete and continuous probability distributions make good projects and illustrations for classroom demonstrations.

We leave the Excel file in [S6] for readers to explore further.

## Example 7. Two-Dimensional Data Table (Generalized Birthday Problem)

The Data Table examples that we have presented so far have examined changes in a single variable. However, we also can vary two variables by using a two-dimensional data table. Here we look at a generalized version of the classical birthday problem [5,10]. As typically presented, in a group of $m$ people chosen at random, we determine the probability that at least two people will share the same birthday. Here we present a model that will determine the smallest number, $m$, of people that must be selected for the probability that at least one duplicate exceeds $p=0.5$.

In fact, we generalize the process to the case of selecting $m$ positive integers at random from the set of the first $n$ positive integers ( $n=365$ gives the birthday problem), and finding the value of $m$ that ensures that the probability of obtaining at least one duplicate value among the $m$ selections exceeds a given probability, $p$. This is useful for illustrating the ideas of the birthday problem with a small class of size $m$ by having the students in the class choose individual integers at random from the set $\{1,2, \ldots, n\}$ instead of using birthdays. We start with the model of Figure 17.

First, we enter values for $n$ (Cell A3) and $p$ (Cell B3). In Column A we let $k$ be a counter for the numbers of items that we are selecting. In Column B we compute the probability, $\mathrm{P}(k)$ that all of the first $k$ selections are different. Clearly, $\mathrm{P}(1)=1$. Then, in computing $\mathrm{P}(k+1)$, we notice that the previous values must all be different, and that $n-k$ will remain. Thus, the probability that the first $k+1$ are all different is $\mathrm{P}(k)(n-k) / n$. We enter this formula in Cell B7 and copy the current entries down their respective columns. The probability that there is at least one repeated value among the first $k$ is computed in Column D as $1-\mathrm{P}(k)$. We find the desired number, $m$, of values needed for the probability to exceed $p$ in Cell C3 by using the form of a table lookup function as in Figure 17b.

|  | A | B | C |
| ---: | ---: | ---: | ---: |
| 1 | Input |  | Output |
| 2 | n | p | num |
| 3 | 365 | 0.5 | 23 |
| 4 |  |  |  |
| 5 | k | all diff | dups |
| 6 | 1 | 1 | 0 |
| 7 | 2 | 0.9973 | 0.0027 |
| 8 | 3 | 0.9918 | 0.0082 |
| 9 | 4 | 0.9836 | 0.0164 |
| 10 | 5 | 0.9729 | 0.0271 |

Figure 17(a). Birthday (output)

|  | A | B | C |
| :---: | :---: | :---: | :---: |
| 1 |  | Input | Output |
| 2 | n | p | num |
| 3 | 365 | 0.5 | =LOOKUP(B3,C6:C105,A6:A105)+1 |
| 4 |  |  |  |
| 5 | k | all different | duplicates |
| 6 | 1 | 1 | =1-B6 |
| 7 | =1+A6 | =(\$A\$3-A6)*B6/\$A\$3 | =1-B7 |
| 8 | $=1+A 7$ | =(\$A\$3-A7)*B7/\$A\$3 | =1-B8 |
| 9 | =1+A8 | =(\$A\$3-A8)*B8/\$A\$3 | =1-B9 |
| 10 | =1+A9 | =(\$A\$3-A9)*B9/\$A\$3 | =1-B10 |

Figure 17(b). Birthday (formulas)

Here $=\operatorname{LOOKUP}(\mathrm{B} 3, \mathrm{C} 6: C 105, \mathrm{~A} 6: A 105)+1$ looks for the value of B3 in the Block C6:C105, and returns the corresponding value in the Block A6:A105. This returns the value of $m$ that gives the last probability that is less than or equal to the probability, $p$, that is being sought. Consequently, we add 1 in order to find the first value that exceeds $p$.

Now we create a 2-dimensional data table as shown in Figure 18(a). In Column F we create ranges of values of $n$ down Column F and probabilities $p$ in Row 2. We then use Excel's Data Table tool (see Figure 19) to fill in the number of integers that must be selected to ensure the probability that there is at least one duplicate exceeds $p$. First, in Cell F2 we enter the formula $=\mathrm{C} 3$, to obtain that number from our choices for $n$ and $p$ in Cells A3:B3.

Figure 19. Two Dimensional Data Table Setup
As in Figure 19, we then use our selection device to highlight the array F2:L12 and select the Data Table command as before, this time entering the values for both $n$ and $p$ as shown in Figure 19. We obtain the output of Figure 18(b). For example, the number of integers that must be selected at random
from a set of $n=100$ integers that will ensure that the probability of at least one duplicate exceeds $p$ $=0.70$ is 16 . We leave the Excel file in [S7] for readers to explore further.

## Example 8. Euler's Phi Function

The field of number theory provides many opportunities to employ a data table approach to classical topics. In this example we look at Euler's phi function [6]. For a positive integer, $n, \varphi(k)$ is the number of positive integers that are less than $k$ and are relatively prime to $k$ (i.e., that have no common divisors with $k$ other than 1 . Thus $\varphi(6)=2$ since only 1 and 5 have no divisors other than 1 in common with 6. In our example we use Excel's greatest common divisor function, $=\operatorname{gcd}()$.

In our model of Figure 20(a) we enter a value for $k$ in Cell A2. We then generate consecutive positive integers, $i$, down Column A and the value of $\operatorname{gcd}(i, k)$ in Column B. In Column C for each $i$ we produce the number 1 if and only if only $k$ and $i$ are relatively prime and $i<k$. Then, in Cell B2, we compute $\varphi(k)$ as the sum of the entries in Column C. The formulas appear in Figure 20(b).

We then use the Data Table command using Columns E:F where the formula in Cell F2 is simply $=\mathrm{B} 2$. We augment our model to indicate prime integers in Column H as those integers, $n$, for which $\varphi(n)=1$. Figure 21 is a graph of the Euler Phi Function, formed from Columns E:F of our model, with points $(n, \varphi(n))$ for $n \leq 1000$.

Figure 21. Euler Phi Function Graph

The field of number theory presents many topics that we can pursue similarly, including prime numbers, factorization, number bases, primitive roots, and indices. We leave the Excel file in [S8] for readers to explore further.

## Example 9: Greatest Common Divisor

In Example 8 we used Excel's built-in greatest common divisor function [6]. However, we can also use a data table together with Euclid's GCD algorithm to produce these greatest common values. That algorithm can be expressed in a sequence of operations that we can implement naturally in a spreadsheet: Suppose that $m$ and $n$ are positive integers with $m>n$. Then, by the standard division algorithm, there are non-negative integers $q_{i}$ and $r_{i}$ so that

$$
\begin{aligned}
& m=q_{1} n+r_{1} \text { with } 0 \leq r_{1}<n \\
& n=q_{2} r_{1}+r_{2} \text { with } 0 \leq r_{2}<r_{1} \\
& r_{1}=q_{3} r_{2}+r_{3} \text { with } 0 \leq r_{3}<r_{2}
\end{aligned}
$$

and so on. Since the $r_{i}$ values are continually decreasing, eventually there is a first value of $k$ for which $r_{k+1}=0$. and $r_{k}$ is the sought for greatest common divisor of $m$ and $n$. See [5].

In Figures 22(a) and 22(b) we present an Excel model for this algorithm. Using this in Figure 22(c) we use the Data Table tool to find the greatest common divisors of $m$ and $n$ for $n=1,2,3, \ldots$

## Example 10. Legislative Apportionment

The process of awarding to regional subdivisions a number of seats in the legislature of a country often is based on population. Surprisingly, each of the usual procedures give rise to paradoxes that have been the subject of controversy and give rise to some interesting mathematics. Both the history and the mathematics involved are presented in [3]. Some other Excel models are contained in [5]. In Figures 23-24 we use Excel's Data Table to examine one process, Webster's Method, that was once used to allocate seats in the United States House of Representatives.

In this model we want to allocate a number of seats (Cell B1) to four states (A,B,C,D), whose populations are given in Column B, with the total computed in Cell B7. In Cell D1 we either enter or create an estimate of the ideal size of seat, here $=\mathrm{B} 7 / \mathrm{B} 1$. We then generate estimates of the number of seats in Column C by dividing each state's population by the estimated seat size. This generally produces non-integers. Webster's method initially awards each state the integer number of seats (Column D) to produce an initial total in Cell D7, with the number of non-allocated seats, $n$, computed in Cell F1. We next use Excel's Rank function in Columns F to rank the remainders, and then in Column G add 1 extra seat to each of the states with the $n$ highest ranks in Column F to produce the allocation for this number of seats. We can then use Excel's Data Table in Columns I:M to produce the allocations to state for different sizes of the legislative body.

|  | A | B | C | D | E | F | G | H | I | J | K | L | M |

| 7 |  | =SUM(B3:B6) |  | =SUM(D3:D6) |  |  | =SUM(G3:G6) |

Figure 24. Apportionment Formulas
Using this model, we can see immediately an anomaly that arises. If the overall number of seats were to increase from 41 to 42 , then State A would lose a seat. Using the Data Table we can examine similarly other surprises that arise with other methods. We leave the Excel file in [S10] for readers to explore further.

## Conclusions

Each author has used Excel extensively as a primary tool in teaching university classes in mathematics and in the computing and information sciences. Excel's data table tool provides teachers with innovative ways to create illuminating mathematical models while equipping their students with beneficial skills in using a powerful mathematical tool of the workplace. The first author also used Excel and the data table to develop and teach live on-line courses from the United States for classes held at Divine Word University in Papua New Guinea.

Our eigenvalue model from linear algebra provides a good pedagogical illustration of our use of Excel. It offers students an accessible way to examine the characteristic function of a square real matrix and to approximate its zeroes without first needing to study the classical algorithms of numerical analysis. If desired, one also can later implement naturally those numerical analysis techniques using Excel.

In our classes students first use these and similar models to observe and investigate their underlying mathematics and subsequently follow up by working on assignments that use data tables. They also can employ data tables in their final course projects with their own applications.

In this paper we have presented only a few topics that can be explored creatively using the Data Table tool. In particular, examples such as creating Bezier curves for numerical analysis, implementing the Sieve of Eratosthenes in number theory, and executing other legislative apportionment algorithms are discussed in [5]. Another interesting application lies in the computation of the probabilities of obtaining false positives in drug testing.
